Data wide and long: reshape(2) melt cast reshape and plyr

- Today we'll look at two data manipulation tools which are flexible and powerful, but easy to use once you grasp a few concepts.
- First is plyr, which extends functional programming tools in R (like lapply) and makes the common data-analysis split-apply-combine procedure easy and elegant.
- Second is reshape(2), which makes it easy to change the format of data frames and arrays from "wide" (observations spread across columns) and "long" (observations spread across rows) formats.
- Both are written by Hadley Wickham (like ggplot2).
- (you can download the knitr source for these slides on my website)

reshape

- plyr is built around the conceptual structure of split-apply-combine
- split your data up in some way.
- apply some function to each part.
- combine the results into the output structure.
- This is a common structure in many data analysis tasks, and R already has some facilities for it.
- plyr unifies these in a single interface and provides some nice helper functions, and also makes the split-apply-combine structure explicit.
- Before we get to plyr itself, let's have a short review of some basic functional programming concepts.

functions: how do they work

LI539 Mixed Effect Models

Dave Kleinschmidt

Introducti

Split-appl combine: plyr

Functions are your friends

apply yourself split-applycombine Convenience functions Use cases Data analysis Modeling

Data wide and long: reshape(2) melt cast reshape

- Formally: take some input, do something, and produce some output.
- You use functions in R all the time.
- Most of the functions you're familiar with have names and are built in (or provided by libraries).

```
mean(runif(100))
## [1] 0.4781
```

- But there's nothing special about functions in R, they're objects, just like any other data type
- This means they can, for instance, be assigned to variables:

```
f <- mean
f(runif(100))
## [1] 0.4859
```

(anonymous) functions: how do they work

LI539 Mixed Effect Models

functions
Use cases
Data
analysis
Modeling
and simu-

Data wide and long: reshape(2) melt cast reshape Functions are objects that are created with the function keyword

```
function(x) sum(x)/length(x)
## function(x) sum(x)/length(x)
## <environment: 0x1044f3710>
```

- Functions are by their nature "anonymous" in R, and have no name, in the same way that the vector c(1,2,3) is just an object, with no intrinsic name (this is unlike other languages, like Java or C).
- New functions can be assigned to variables to be called over and over again

```
mymean <- function(x) sum(x)/length(x)
mymean(runif(100))
## [1] 0.467
mymean(runif(100, 1, 2))
## [1] 1.529</pre>
```

...or just evaluated once

```
(function(x) sum(x)/length(x)) (runif(100))
## [1] 0.5171
```

(notice the parentheses around the whole function definition)

functions, environments, and closures

Data wide and long: reshape(2) melt cast reshape

- A function object lists an environment when it's printed to the console
- This is because functions are really closures in R.
- They include information about the values of variables when the function was created.
- You can take advantage of this to make "function factories":

```
make.power <- function(n) {
  return(function(x) x^n)
}
my.square <- make.power(2)
my.square(3)
## [1] 9
(make.power(4)) (2)
## [1] 16</pre>
```

 See Hadley Wickham's excellent chapter on functional programming in R for more on this: https://github.com/hadley/devtools/wiki/ Functional-programming

Data wide
and long:
reshape(2)
melt
cast
reshape

- Function declarations have three parts:
 - The function keyword
 - 2 Comma-separated list of function arguments
 - The body of the function, which is an expression (multi-statement expression should be enclosed in braces {}). The value of the expression is used for the returned value of the function if no return statement is encountered in the body.
- For instance:

```
mean.and.var <- function(x) {
  m <- mean(x)
  v <- var(x)
  data.frame(mean=m, var=v)
}</pre>
```

a few function tips

apply yourself split-applycombine Convenience

functions
Use cases

Data analysis Modeling and simulation

Data wide and long: reshape(2) melt

reshape

 The ellipsis . . . can be included in the arguments list and "captures" any arguments not specifically named. This is useful to pass on other arguments to other function calls in the body (as we'll see later).

- You can specify default values for arguments by argument=default.
- R has very sophisticated argument resolution when a function is called. It
 first assigns named arguments by name, and then unnamed arguments
 are assigned positionally to unfilled arguments. So you can say something
 like

```
sd(rnorm(sd=5, mean=1, 100))
## [1] 4.912
```

where the last argument is interpreted as n, even though the specification of rnorm calls for n to be first:

```
rnorm
## function (n, mean = 0, sd = 1)
## .Internal(rnorm(n, mean, sd))
## <br/>
## <br/>
## sytecode: 0x104989510>
## <environment: namespace:stats>
```

Your first foray into functional programming

apply yourself split-apply-

Combine Convenience functions Use cases Data

Use cases
Data
analysis
Modeling
and simulation

Data wide and long: reshape(2) melt cast reshape

- R is a functional programming language at its heart.
- One of the most basic operations of functional programming is to apply a function individually to items in a list.
- In base R, this is done via lapply (for list-apply) and friends:

```
list.o.nums <- list(runif(100), rnorm(100), rpois(100, lambda=1))
lapply(list.o.nums, mean)

## [[1]]
## [1] 0.4703
##
## [[2]]
## [1] 0.03472
##
## [[3]]
## [1] 0.89</pre>
```

 The "big three" apply functions in R are lapply (takes and returns a list), sapply (like lapply but attempts to simplify output into a vector or matrix), and apply (which works on arrays).

unleash the power of anonymous functions

LI539 Mixed Effect Models

Dave Kleinschmidt

Introducti

Split-apply combine: plyr

Functions are your friends apply

yourself split-applycombine

Convenien functions Use cases Data analysis Modeling and simu-

Data wide and long: reshape(2) melt cast reshape

- When combined with lapply and friends, anonymous functions are extremely powerful.
- You could, for instance, run a simulation with a range of parameter values:

```
sapply(1:10, function(n) rpois(5, lambda=n))
        [,1] [,2] [,3] [,4] [,5]
                                   [,6]
                                         [,7] [,8]
## [1,]
           0
                                           10
                                                       6
   [2.]
                                            9
                                                      17
## [3.]
                                                      12
           0
## [4.]
                                                      15
                                                              9
## [5.]
           Ω
                 3
                                                              6
```

 Or repeat the same simulation multiple times, calculating a summary statistics for each repetition:

```
sapply(1:10, function(n) mean(rnorm(n=5, mean=0, sd=1)))
## [1] 0.20120 0.03167 0.49330 -0.07796 0.08483 0.01232 -0.68791
## [8] -0.21145 0.13870 -0.52366
```

Dave Kleinschmidt

Introduction

Split-apply combine: plyr

Functions are your friends apply

split-applycombine

Convenience functions Use cases Data analysis Modeling and simulation

and long: reshape(2) melt

reshape(2) melt cast reshape and plyr

- This is a common data-analysis task: split up the data in some way, analyze each piece, and then put the results back together again.
- The plyr package (Wickham, 2011) was designed to facilitate this process.
- For instance, instead of that split/sapply combo, we could use the ddply function:

LI539 Mixed Effect Models

Dave Kleinschmidt

Introduct

combine: plyr Functions are your friends

split-applycombine

Convenience functions Use cases Data analysis Modeling and simulation

Data wide and long: reshape(2) melt cast

The ddply call has three parts:

```
ddply(lexdec, .(Subject), function(df) data.frame(RT.mean=mean(df$RT)))
```

- 1 The data, lexdec
- The splitting variables, .(Subject). The .() function is a utility function which quotes a list of variables or expressions. We could just as easily have used the variable names as strings c("Subject") or (one-sided) formula notation ~Subject.
- The function to apply to the individual pieces. In this case, the function takes a data.frame as input and returns a data.frame which has one variable—RT.mean. The splitting variables are automatically added before the results are combined.

plyr functions: input

LI539 Mixed Effect Models

Dave Kleinschmidt

Introducti

Split-apply combine: plyr

Functions are your friends apply

split-applycombine

Convenience functions Use cases Data analysis Modeling and simu-

Data wide and long: reshape(2) melt cast reshape

- Plyr commands are named based on their input and output.
- The first letter refers to the format of the input.
- The input determines how the data is split:
 - d*ply(.data, .variables, .fun, ...) takes data frame input and splits it into subsets based on the unique combinations of the .variables.
 - 1*ply(.data, .fun, ...) takes list input, splitting the list and passing each element to .fun.
 - a*ply(.data, .margins, .fun, ...) takes array input, and splits it into sub arrays by .margins (just like base R apply). For instance, if .margins = 1 and .data is a three-D array, then .data[1, ,], .data[2, ,], ... are each passed to .fun.

plyr functions: output

LI539 Mixed Effect Models

Dave Kleinschmidt

Introducti

Split-apply combine: plyr Functions are your friends

apply yourself split-applycombine

Convenience functions Use cases Data analysis Modeling and simulation

Data wide and long: reshape(2) melt cast reshape

- The second letter of the command name refers to the output format
- The output determines how the data is combined at the end:
 - *dply takes the result of its .fun and turns it into a data frame, then adds the splitting variables (values of .variables for ddply, list names for ldply, or array dimnames for adply) before rbinding the individual data frames together
 - *lply just returns a list of the result of applying .fun to each individual split, just like lapply, but additionally adds names based on the splitting variables.
 - *aply tries to assemble the output of .fun into a big array, where the
 combine dimensions are the last ones. For instance, if .fun returns a
 two-dimensional array (always of the same size), and there were three
 splitting variables or dimensions originally, then the output would be a
 five-dimensional array, with dimensions 1 to 2 corresponding to the .fun
 output dimensions and 2 to 5 the splitting variables.

try it: output behavior of plyr commands

LI539 Mixed Effect Models

Dave Kleinschmidt

Introductio

Split-applycombine: plyr Functions are your friends apply yourself

split-applycombine

Convenience functions Use cases Data analysis Modeling and simulation

Data wide and long: reshape(2) melt cast reshape and plyr

Task

Let's use the lexdec data set to explore the output behavior of plyr. Start with this ddply call (copy and paste from the slides pdf, or from the accompanying .R file):

```
library(plyr)
data(lexdec, package='languageR')  # load the dataset if it isn't already
ddply(lexdec, .(PrevType, Class), function(df) with(df, data.frame(meanRT=mean(RT))))
```

- What does this do? Look at the lexdec data frame, run the command, and interpret the output.
- ② Are these numbers "really" different? Change the function to also return the variance (or standard deviation or standard error, or whatever other measure you think might be useful).
- Change it to return a list instead using dlply. The output might look a little funny. Why? Use str to investigate the output.
- Now make it return an array using daply. The output will probably look totally wrong. Why? (Hint: use str to look at the output, again). Fix it so that it does what you'd expect/like it to do.

friends
apply

Convenience functions Use cases Data analysis Modeling

split-apply-

Data wide and long: reshape(2) melt cast reshape and plyr

- An added level of convenience comes from the fact that any extra arguments to, e.g., ddply are passed to the function which operates on each piece
- This means you can use functions like subset or transform which take a
 data frame and return another data frame.
- For instance, to find the trial with the slowest RT for each subject, split by Subject and then use subset:

```
slowestTrials <- ddply(lexdec, .(Subject), subset, RT==max(RT))
head(slowestTrials[, c('Subject', 'RT', 'Trial', 'Word')])
     Subject
                RT Trial
##
                              Word
## 1
          A1 7 115
                      79 tortoise
          A2 6.832
                      66
## 2
                              lion
## 3
          A3 7 132
                     157
                            radish
## 4
           C 6.680
                     145
                              frog
           D 6.984
                    172

## 6
                             snake
```

• This is equivalent to both

```
ddply(lexdec, .(Subject), function(df, ...) subset(df, ...), RT==max(RT))
ddply(lexdec, .(Subject), function(df) subset(df, RT==max(RT)))
```

transform

LI539 Mixed Effect Models

Dave Kleinschmidt

Introducti

Split-apply combine: plyr Functions are your friends apply

Convenience functions Use cases Data analysis Modeling

and simu-

split-apply-

Data wide and long: reshape(2) melt cast reshape Another super convenient function is transform, which adds variables to
a data frame (or replaces them) using expressions evaluated using the
data frame as the environment (like the with function).

- For instance, we often standardize measures before regression (center and possibly scale).
- If the reaction time distributions of individual subjects are very different, then we might want to standardize them for each subject individually. In "verbose" ddply, we could do

```
ddply(lexdec, .(Subject), function(df) {
    df$RT.s <- scale(df$RT)
    return(df)
})</pre>
```

• However, we can be more concise using transform:

```
lexdecScaledRT <- ddply(lexdec, .(Subject), transform, RT.s=scale(RT))</pre>
```

This expresses very transparently what we're trying to do: transform the data by adding a variable for the scaled (zero mean and unit sd) reaction time.

Task

Let's investigate the relative ordering of RTs for different words

- Add a new variable RTrank which is the rank-order of the RT for each trial, by subject. That is, RTrank=1 for that subject's fastest trial, 2 for the second-fastest, etc. Hint: rank finds the rank indices of a vector.
- ② Find the average RT rank for each word, using summarise.
- Plot the relationship between the word frequencies and their average rank.
 - If you're feeling fancy, put errorbars on the words showing the 25% and 75% quantiles.
 - Which word has the highest average RT rank? The lowest?

reshape

- Let's check to see whether the errors in lexdec responses are evenly distributed across native and non-native speakers.
- There are a couple of ways to do this. We could use ddply and summarise like above:

 We could also use daply to get an array of raw counts of correct and incorrect responses, by splitting on NativeLanguage and Correct and then extracting the number of rows in each split:

```
daply(lexdec, .(NativeLanguage, Correct), nrow)

## Correct

## NativeLanguage correct incorrect

## English 920 28

## Other 674 37
```

Checking distribution of errors

Data analysis Modeling and simulation

Data wide and long: reshape(2) melt cast reshape

- Let's estimate the effect of frequency on RT for each subject separately (perhaps to get a sense of whether to include random slopes in a mixed effects model).
- We can do this using a combination of ddply and coef:

```
\verb|subjectSlopes <- ddply(lexdec, .(Subject), function(df) {| coef(lm(RT^Frequency, data=df))|}| \\
```

• We can see that these slopes show a fair amount of variability,

```
summary(subjectSlopes$Frequency)
## Min. 1st Qu. Median Mean 3rd Qu. Max.
## -0.09810 -0.05380 -0.03830 -0.04290 -0.02830 -0.00403
```

so it might make sense to include random slopes in later regression modeling.

pata wide and long: reshape(2) melt cast reshape

- ...but wait.
- Calculating the standard error in this way assumes that, for the purposes
 of comparing the condition means, each observed RT is an independent
 draw from the same normal distribution.
- But in fact, they are not: observations are grouped both by subject and by item (word).
- One way of dealing with this: look at the by-subject standard error, by averaging within each subject and then treating each subject as an independent draw from the underlying condition.
- This is the "by-subject" analysis, like the "F1" ANOVA.

by-subject standard errors with ddply

Task

- Use ddply to do the "F2" or by-item analysis, finding by-item standard errors, treating the words as items.
- Plot the resulting errorbars, and use this (and the actual ddply output) to interpret the results.

- The plyr functions m*ply and r*ply are wrappers for other forms which
 make simulations more convenient. Check out the documentation
 (?mdply) and the plyr article in J. Stat. Software.
- Because they combine things in nice ways, plyr functions can help R data functions play nicely together.
 - To concatenate a list of data frames into one big data frame, you can use ldply(list.of.dfs, I) (the identity function I just returns its input).
 - To "shatter" an array into a data frame where the dimension names are stored in columns, you can use adply(an.array, 1:ndim(an.array), I).
 Any margins left out then index rows. If any dimensions are named, they will be transferred to the data frame in a smart way.
- Use subset and ddply to remove outliers subject-by-subject
- Check balance (number of trials/subjects in each condition) using nrow and ddply of daply (like the correct/incorrect example).

apply yourself split-apply-combine Convenience functions Use cases Data analysis Modeling and simulation

Data wide and long: reshape(2) melt cast reshape and plyr

- The best way to understand a model is to simulate fake data and see what the model does with it.
- Frequently the process goes as follows:
 - Pick some range of parameter values (random effect variance vs. residual variance).
 - @ Generate some data using those parameters
 - Fit model to that data, and record summary statistics.
- This fits well within the split-apply-combine pattern of plyr.
- For example, let's look at how not accounting for random slopes and intercepts inflates Type I error rates.
- We'll generate fake data for a binary "frequency" variable which has a true effect of 0, then fit lm and lmer models with random intercept and slope.
- Let's start simple, fitting the models to one set of parameters, repeating the simulation 100 times.

Data
analysis
Modeling
and simu-

Data wide and long: reshape(2) melt cast reshape

- What if we want to run the simulation with different sets of parameter values?
- Create a data frame of parameters, using expand.grid on arguments which have the same names as the arguments to make.data.generator.

• And then use mdply on the result.

digression: mdply

LI539 Mixed Effect Models

Dave Kleinschmidt

Introduction

Split-applycombine: plyr Functions are your friends apply yourself split-applycombine Convenience functions Use cases Data analysis Modeling

```
Data wide
and long:
reshape(2)
melt
cast
reshape
```

and simu-

```
mdply(params, function(...) {
  make.data <- make.data.generator(...)
  rdply(.n=100, fit.models(make.data()))
}, .progress='text')</pre>
```

- mdply is like Map: it passes the variables in a data frame (split row-by-row) as named arguments to the function. The function(...) {} syntax means that the function will accept any named arguments, and then recycle them wherever the ... occurs anywhere inside the body. Thus, this mdply will pass the columns of params as arguments to the make.data.generator() function, no matter which parameters you specify.
- This specific example (where the parameters are n.obs and n.subj) is equivalent to:

```
ddply(params, .(n.obs, n.subj), function(df) {
   make.data <- make.data.generator(n.obs=df$n.obs, n.subj=df$n.subj)
   rdply(.n=100, .fun=fit.models(make.data()))
}, .progress='text')</pre>
```

##	3	A3	<na></na>	<na></na>	<na></na>
##	4	C	6.533789	correct	<na></na>
##	5	D	<na></na>	<na></na>	6.232448

long Each observation gets exactly one row, with values in "id" columns giving identifying information (like subject, trial, whether the observed value is a correct/incorrect response or a RT observation, etc.)

wide Each row contains all the observations for a unique combination of identifying variables (say, one subject). Column names identify the kind of observation in that row (trial number, observation type).

melt cast reshape

- To specify the measure and id variables, use measure.vars= and id.vars= arguments.
- You can specify them as indices (column numbers) or names.
- melt will try to guess the id and measure variables if you don't specify them.
- If you specify only measure vars, melt will treat the other variables as id variables (and vice-versa)
- If you want some variables ommitted, specify the measure and id variables that you want and the others will be dropped.

melt cast

reshape

- melt gets your data into a "raw material" that can be easily converted to other more useful formats.
- Molten data can be converted to different shapes using the *cast commands.
- dcast creates a data frame, and acast creates an array.
- Both commands take molten data and a formula which defines the new shape.

> melt cast reshape

- dcast takes a two-dimensional formula. The left hand side tells which variables determine the rows, and the right side the columns
- Let's put RT and correct in their own columns. The ld.m\$measure variable indicates whether the ld.m\$value is an RT or a correct measure, so we put that variable on the right-hand side of the formula.

```
head(dcast(ld.m. Subject+Trial ~ measure))
     Subject Trial Correct
                                  RT
               100 correct 6.126869
          A1
          A1
               102 correct 6.284134
          Δ1
               106 correct 6 089045
          Δ1
               108 correct 6 383507
          A1
               109 correct 6.22059
          Δ1
               111 correct 6.381816

Data wide and long: reshape(2)

melt cast reshape and plyr We can also use the shorthand ... to indicate all other (non-value) variables:

```
head(dcast(ld.m. ... ~ measure))
                variable Trial Correct
     Subject
## 1
          Δ1
                   23 RT
                                   <NA> 6.340359
          A1 23_Correct
                             23 correct
                                             <NA>
                   27 RT
                                   <NA> 6.308098
          A1
          A1 27 Correct
                                             <NA>
                             27 correct
                   29 RT
          A 1
                                   <NA> 6.349139
          A1 29_Correct
                             29 correct
                                             <NA>
```

 But this is no good here because ld.m\$variable also encodes information about measure, so we have to remove it first to be able to use ...

```
ld_m$variable <- NULL
head(dcast(ld.m. ... ~ measure))
     Subject Trial Correct
          A 1
               100 correct 6.126869
          A1
               102 correct 6.284134
## 3
          Δ1
               106 correct 6 089045
          Δ1
               108 correct 6 383507
               109 correct 6.22059
          A1
          Δ1
               111 correct 6.381816
## 6
```

melt cast reshape

- Specify the shape of the "cast" data using a formula. For each
 combination of the values of variables on the left-hand side, there will be
 one row, and likewise for columns with the right-hand side.
- For dcast, the data frame will also have left-hand variables in columns in the resulting data frame. Right-hand variables will have their values pasteed together as column names for the other columns.
- If you want higher-dimensional output, you can use acast which creates an array (specify dimensions like dim1var1 ~ dim2var1 + dim2var2 ~ dim3var1).
- If there is no variable called value, then cast will try to guess. You can
 override the defaults by specifying the value.var= argument.

melt
cast
reshape

- If the formula results in more than one value in each cell, you need to specify an aggregating function (like in ddply) via the fun.aggregate= argument (you can abbreviate to fun.agg=).
- The default is length which tells you how many observations are in that cell.

 The function you specify must return a single value (more constrained than plyr).

"but can't I just do this in Excel?"

melt cast reshape

- You can!
- But it will be tedious and you will make mistakes.
- Using tools designed for these data-manipulation tasks makes you be explicit about the things you are doing to your data.
- And when you are done, you have a script which is a complete record of what you did (and, if you're using knitr, a nicely formatted report, too).

> reshape and plyr

- The reshape library operations are conceptually related to the split-apply-combine logic of plyr.
- Question: what's the plyr equivalent of the melt command we saw before?

```
melt(ld.wide, id.var='Subject', na.rm=T)
```

 Remember what melt does: split the data by the id variables, and rearrange the measure variable columns so that they're in one value column, moving the column names into a new variable column.

Question: how would you write the dcast command from before?

```
head(dcast(ld.m, Subject+Trial ~ measure))
```

```
head(ddply(ld.m, .(Subject, Trial), function(df) {
 res <- data.frame(t(df$value))
  names(res) <- df$measure
 return(res)
}))
##
     Subject Trial
